

DATA TYPE PRESERVING ENCRYPTION

Field of invention

The present invention generally relates to the field of data encryption and specifically to a method and a system for data type preserving encryption of a data element in a relational database.

Background of the invention

It is common to use client-server solutions for commercial applications. Hereby a separation of applications and data storage is provided. Development of applications and products for data storage and retrieval can be and is generally therefore also separated. One way of storing data is using a database as a structured and unified way of storage and retrieval. A standardized communication interface, such as SQL, is then usually used for data retrieval and storage in the databases in order to let application developers develop applications independently of the database software. In the software market of today, the development of database and application software is generally performed by different vendors.

The database vendors provides a framework and tools for storing and retrieving data, but it is up to the application developer to define the logical structure and design of the database. This is done through said communication interface. Design comprise issues like implementing the data model in tables in the database. The tables utilizes rows for representing data records and columns for different properties of a data record. Thus, a data element represent a property of a specific data record, i.e. a combination of a row and a column of a table. The restrictions and constraints of a data element in a database is defined by its type. The data type could for instance restrict which characters, the

length of the data element, etc that can be stored in the database. The restrictions defined by the data type vary among the databases provided by different vendors.

In order to provide protection for data in
5 databases, it is preferred to use a so-called granular security solution for the encryption of databases, instead of building walls around servers or hard drives. In such a solution, which is described in the document WO 97/49211 by the same applicant, a protective layer of
10 encryption is provided around specific sensitive data-items or objects. This prevents outside attacks as well as infiltration from within the server itself. This also allows the administrator of the security solution to define which data stored in databases are sensitive and
15 thereby focusing the protection only on the sensitive data, which in turn minimizes the delays or burdens on the system that may occur from other bulk encryption methods. Most preferably the encryption is made on such a basic level as in the data element level of the
20 databases. Such security solutions are often provided between the database and the application intercepting the interface in between. Thus, they are transparent to the application.

However, when implementing security solutions for
25 protecting individual data elements, such as the above described, the database design has to be adapted in order to accommodate the particular needs of a security solution. Any manipulation of the database design and structure will result in a cumbersome installation
30 process and also increased maintenance costs. For example, if the structure of a database table has to be changed in order to accommodate an encrypted data element, this would require a costly conversion of the database table, especially if the table is populated with
35 data. Such a change could be to introduce a new or change the properties of an existing column. Then, the interface between the application and the database has to be

25

30

35

Hereby, a method is provided which reduces the need for changes to the database design by preserving the data type in the encrypted data element. The preservation means that the ciphertext is as valid as the plaintext it replaces. Then using this method for encryption of individual data elements will not require a change of the data type of the data element which is to be encrypted.

Thus, a security solution is provided which is both application transparent and database table transparent. This results in easier installation of the security solution and simplified maintenance of both the security solution and the database.

[illegible]

controlled to provide encryption that results in a data element having the same number of characters as the unencrypted data element.

In an embodiment the method comprises the further
 5 step of arranging one or more character sets in a pattern for a data type. Hereby, the work needed for interpreting a data type and form restricting character sets is reduced to reading a pattern corresponding to the data type. For example, a data type restricting the data of
 10 the data element to integers would result in a pattern of consecutive character sets containing the numerals 0-9. Thus, such a pattern would facilitate the interpreting process in the previously mentioned step.

In a preferred embodiment of the present invention,
 15 the method comprises the further steps of converting each character to an index value and adding a varying value to each index value before encryption. Hereby, a method is provided which reduces the risk for encrypting adjacent characters the same way when similar characters occur in
 20 sequence. Preferably, the varying integer value is obtained by the steps of: creating an initial value by hashing the encryption key; adding adjacent index values pairwise from the left to the right using said initial value when adding the leftmost character.

Also according to the invention a system for data
 25 type preserving encryption of a data element in a relational database, comprising: a database, wherein said database comprises a plurality of data elements of at least one type, and each data element comprises a string
 30 of at least one character, comprising the steps of: reading means for reading the type of a data element which is to be encrypted; interpretation means for interpreting said data type in order to form a restricting character set for each character of said data
 35 element; and encryption means for encrypting each character of said data element into an encrypted character using said restricted character set to control

said encryption means to only create encrypted characters included said restricting character set.

The advantages of the system according to the invention corresponds to those of the inventive method.

Brief description of the drawings

For exemplifying purposes, the invention will be described to embodiments thereof illustrated in the attached drawings, wherein:

10 Fig. 1 is a schematic view of an applicable environment for the method according to the invention; and

Fig. 2 is a flow-chart illustrating a method according to an embodiment of the invention.

15

Description of preferred embodiments

The inventive method is a method for data type preserving encryption of a data element in a relational database. The method provides a new way of using security solutions on databases, since the need for redesigning the database is significantly reduced. The method will now be described in an example of an applicable environment illustrated in fig. 1. The environment comprises an application 10, encryption means 20 and a database 30. The database comprises a plurality of data elements 31, each associated with a data type 32. The data type defines at least the valid characters of the data element. Common data types used in commercial databases are for instance INTEGER, FLOAT, CHAR, BOOLEAN, and DATE. These correspond to integers, floating numbers, all alphanumerical characters including non-alphabetical letters, a true or false value, and date, respectively. In most cases these are specified with an appropriate length for each data element. In some instances the length is naturally defined by the data type, such as for the DATE format.

The application 10 is connected to the database 30 in order to store at least some of its data, for example personnel records. The data element which is subject for encryption is then encrypted in the encryption means 20.

- 5 Utilizing encryption means below the application makes the encryption application transparent. Thus, the encryption means is provided for intercepting data storage and retrieval requests from the application. Preferably, the rules defining which data elements that
- 10 are to be encrypted is set up in the encryption means leaving the database and the application unaffected. With the inventive method the security solution will also be database table transparent since the database design will be unaffected when introducing encryption for a data
- 15 element.

- The invention will now be illustrated by how a data element is encrypted with the inventive method. Referring to fig. 2, a method for data type preserving encryption of a data element in a relational database according to a
- 20 preferred embodiment of the invention is now to be described.

- The method comprises a first step S1, wherein an index value is provided for each character. This could preferably be done in advance for all available characters,
- 25 i.e. all letters, numbers, special characters, control characters, etc, that are used in the database. Preferably this is done by taking the ASCII value of each character. However, this could also be done at the time for encryption of each character of the data element
- 30 which is to be encrypted in the encryption means. For instance "A" could be represented by "1", "B" by "2", etc.

- Then, when a data element is to be written to the database by the application 10, the encryption means have
- 35 to know the data type of the data element where the data is to be stored. The data type is read in the step S2.

In order to ensure that the encrypted values of two single character strings with adjacent characters will not be sequential, the index values could preferably themselves be shuffled based on a portion of the encryption key. For instance, it is not desired to let "b" be encrypted as "y" whenever "a" is encrypted as "x". Then in a step S4, the data is "rippled" from the left to the right and preferably again from the right to the left. This could be done by hashing the encryption key into an initial value and add adjacent values pairwise. Then, as preferred, the same procedure is applied to the permutation of the individual characters. Now the fact that two strings that contain the same characters is disguised.

1. The DES algorithm takes as input a 64-bit input block and a 64-bit key (56 key bits and 8 parity bits) and uses these two values to produce a 64-bit output. The ciphertext output can be decrypted using the same key.

3. At the end of each encryption pass, the plaintext data is also shifted into the DES input register by the steps of:

$$i_1 \ i_2 \ i_3 \ i_4 \ \dots \ i_8$$

5 a1 a2 a3 a4 ... a8
wherein each value represents an 8-bit number (0-255).

```
10      d. The first transformed index value is the modular
      sum:
```

```

15      e. constructing a new DES input value as:
           b2 b3 b4 ... b8 i1

```

20 c1 c2 c3 c4 ... c8

$$z_2 = c_8 + i_2 \pmod{I}.$$

z1 z2 z3 ... zN

Here every character in the restricting character
35 set is given an sequential ordinal, and the highest
number represent the size, I, of the restricting
character set. In this embodiment each individual
